Abstract

We have developed PGPG (Pipeline Generator for Programmable GRAPE), a software which generates the low-level design of the pipeline processor and communication software for FPGA-based computing engines (FBCEs). An FBCE typically consists of one or multiple FPGA (Field-Programmable Gate Array) chips and local memory. Here, the term “Field-Programmable” means that one can rewrite the logic implemented to the chip after the hardware is completed, and therefore a single FBCE can be used for calculation of various functions, for example pipeline processors for gravity, SPH interaction, or image processing. The main problem with FBCEs is that the user need to develop the detailed hardware design for the processor to be implemented to FPGA chips. In addition, she or he has to write the control logic for the processor, communication and data conversion library on the host processor, and application program which uses the developed processor. These require detailed knowledge of hardware design, a hardware description language such as VHDL, the operating system and the application, and amount of human work is huge. A relatively simple design would require 1 person-year or more. The PGPG software generates all necessary design descriptions, except for the application software itself, from a high-level design description of the pipeline processor in the PGPG language. The PGPG language is a simple language, specialized to the description of pipeline processors. Thus, the design of pipeline processor in PGPG language is much easier than the traditional design. For real applications such as the pipeline for gravitational interaction, the pipeline processor generated by PGPG achieved the

performance similar to that of hand-written code. In this paper we present a detailed description of PGP version 1.0.

Key words: methods: n-body simulations, methods: numerical

1. Introduction

Astronomical many-body simulations have been widely used to investigate the formation and evolution of various astronomical systems, such as planetary systems, globular clusters, galaxies, clusters of galaxies, and large scale structures. In such simulations, we treat planetesimals, stars, or galaxies as particles interacting with each other. We numerically evaluate interactions between the particles and advance the particles according to Newton's equation of motion.

In many cases, the size of an astrophysical many-body simulation is limited by the available computational resources. Simulation of pure gravitational many-body system is a typical example. Since the gravity is a long-range interaction, the calculation cost is $O(N^2)$ per timestep for the simplest scheme, where N is the number of particles in the system. We can reduce this $O(N^2)$ calculation cost to $O(N \log N)$, by using some approximated algorithms, such as the Barnes-Hut treecode (Barnes, Hut 1986), but the scaling coefficient is pretty large. Thus, the calculation of the interaction between particles is usually the most expensive part of the entire calculation, and thus limits the number of particles we can handle. Smoothed Particle Hydrodynamics (SPH, Lucy 1977, Gingold, Monaghan 1977), in which particles are used to represent the fluid, is another example. In SPH calculations, hydrodynamical equation is expressed by short-range interaction between particles. The calculation cost of this SPH interaction is rather high, because the average number of particles which interact with one particle is fairly large, typically around 50, and the calculation of single pairwise interaction is quite a bit more complex compared to gravitational interaction.

Astrophysics is not the only field where the particle-based calculation is used. Molecular dynamics (MD) simulation and boundary element method (BEM) are examples of numerical methods where each element of the system in principle interacts with all other elements in the system. In both cases, approaches similar to Barnes-Hut treecode or FMM (Greengard, Rokhlin 1987) help to reduce the calculation cost, but the interaction calculation dominates the total calculation cost.

One extreme approach to accelerate the particle-based simulation is to build a special-purpose computer for the interaction calculation. Two characteristics of the interaction calculation make it well suited for such approach. Firstly, the calculation of pairwise interaction is relatively simple. In the case of gravitational interaction, the total number of floating-point operations (counting all operations, including square root and divide operations) is only 20. So

it is not inconceivable to design a fully pipelined, hardwired processor dedicated to the calculation of gravitational interaction. For other application like SPH or molecular dynamics, the interaction calculation is more complicated, but still hardware approach is feasible. Secondly, the interaction is in its simplest form all-to-all. In other words, each particle interacts with all other particles in the system. Thus, there is lots of parallelism available. In particular, it is possible to design a hardware so that it calculate the force from one particle to many other particles in parallel. In this way we can reduce the required memory bandwidth. Of course, if the interaction is of short-range nature, one need to implement some clever way to reduce calculation cost from $O(N^2)$ to $O(N)$, and the reduction in the memory bandwidth is not as effective as in the case of true $O(N^2)$ calculation.

The approach to develop specialized hardware for gravitational interaction, materialized in the GRAPE ("GRAvity piPE") project (Sugimoto et al. 1990; Makino and Taiji 1998), has been fairly successful, achieving the speed comparable or faster than the fastest general-purpose computers for the price tag one or two orders of magnitude smaller. For example, GRAPE-6, which costed 500M JYE, achieved the peak speed of 64 Tflops. This speed is favorably compared to the peak speed of the Earth Simulator (40Tflops) or ASCI-Q(30Tflops), both costed several tens of billions of JYE. A major limitation of GRAPE is that it cannot handle anything other than the interaction through $1/r$ potential. It is certainly possible to build a hardware that can handle arbitrary central force, so that molecular dynamics calculation can also be handled (Ito et al. 1993; Fukushima et al 1996; Narumi et al. 1999; Taiji et al 2003).

However, to design a hardware that can calculate both the gravitational interaction and, for example, an SPH interaction is quite difficult. Actually, to develop the pipeline processor just for SPH interaction turned out to be a rather difficult task (Yokono et al. 1999). This is provably because the SPH interaction is much more complex than gravity.

Computing devices which uses FPGA (Field-Programmable Gate Array) chips could offer the level of flexibility that was impossible to achieve with the conventional GRAPE approaches. As its name suggests, FPGA is a mass-produced LSI chip, consisting of a large number of logic elements and switching network. By programming these logic elements and switching network, we can implement an arbitrary logic design, as far as it can fit to the chip used. Thus, a single hardware can be used to implement various pipeline processors, such as that for gravity, SPH, and others. Such FPGA-based "reconfigurable" computing device has been an active area of research since Splash-1 and Splash-2 (Buell et al. 1996), and several groups, including ourselves, have tried to apply the idea of reconfigurable computing to particle simulations (Kim et al. 1995, Hamada et al. 2000, Spurzem et al. 2002). Hamada et al. (2000) called this approach "Programmable GRAPE" or PROGRAPE.

Figure 1 shows the basic structure of a PROGRAPE system. It consists of a programmable GRAPE hardware and a host computer. The programmable GRAPE hardware typically is composed of FPGA chips to which the interaction pipelines are implemented, a

Fig. 1. Basic structure of a programmable GRAPE(PROGRAPE).

particle memory, and an interface unit, and calculates the interaction $\mathbf{f}_i$ between i -the particle and other particles expressed as

$$\mathbf{f}_i = \sum_j \mathbf{G}(\mathbf{a}_i, \mathbf{a}_j), \quad (1)$$

where $\mathbf{a}_i$ is the physical value of the i -th particle, such as position and velocities, and $\mathbf{G}()$ is a user-specified function. We specify the function $\mathbf{G}()$ by programming FPGA. The physical values $\mathbf{a}_j$ of all particles are stored in the particle memory and supplies them to the interaction pipeline. The physical values $\mathbf{a}_i$ are stored in registers of the interaction pipeline. The interface unit controls communications between the programmable GRAPE hardware and the host computer. The host computer performs all other calculations.

FPGA-based PROGRAPEs have several important advantages over conventional full-custom GRAPE processors. One is that the development cost of the chip itself is paid by the manufacturer of the chip, not by us. Thus, initial cost is much lower. This low development cost means that new hardwares can be developed in shorter cycle. Large GRAPE hardwares took several years to develop, and this means the device technology used in GRAPE hardwares, even at the time of its completion, is a few years old. This delay implies quite a large performance hit.

Thus, even though the efficiency in the transistor usage is much worse than full-custom GRAPE processors, the actual price-performance of a PROGRAPE system is not so bad, if one condition is satisfied: If the design of the pipeline processor to be implemented in FPGA and other necessary softwares can be developed sufficiently fast. Previous experiences tell us that it is not the case. To implement a relatively simple pipeline for gravitational interaction calculation took more than one person-year, and implementation of even a simple SPH pipeline would take much more. Thus, clearly the difficulty of the software development has been the limiting factor for the practical use of PROGRAPE or other FPGA-based computing device.

The difficulty is partly because we have to design the interaction pipeline itself, for which we need rather detailed and lengthy description of hardware logic in hardware-description languages such as VHDL. In addition to the pipeline itself, we also need to develop the control logic for the pipeline and communication to the host, driver software on the host computer,

and software emulator library used to verify the design (see section 2).

In theory, most of the design description of softwares and hardwares, including the bit-level design of the interaction pipeline itself, can be automatically generated from some high-level description of the pipeline itself. The basic idea behind the PGP (Pipeline Generator for Programmable GRAPE) system, which we describe in this paper, is to realize such automatic generation. PGP generates all necessary hardware design descriptions and driver softwares, from high-level description of the pipeline processor itself. Thus, the user is relieved of the burden of learning complex VHDL language. Also, the driver software is automatically generated, so that the user can concentrate on writing the application program, not the low-level driver software for a specific hardware. Thus, we can dramatically reduce the amount of the work of the application programmer. More importantly, when a new hardware becomes ready, once the PGP system is ported, all user applications developed on it works unchanged. The effort spent to design one application on one hardware will not be thrown away when new hardware becomes available.

In this paper, we describe the PGP system version 1.0. In section 2, we describe the traditional design flow and its problem. In section 3 we describe the basic concept and structure of PGP. In section 4, we show a design of gravitational force pipeline as an example of pipeline generated by PGP. Section 5 is for discussion. Table 1 is a glossary for abbreviations used in the paper.

2. Traditional Design Flow for FPGA-based Computing Engines

In the traditional design flow, we design the FPGA-based computing system in the following five steps.

(A) Target Function Specification:

We specify the target function, namely the function that the pipeline processor calculates. This includes the specification of the input data (number format and word length), the dataflow for the calculation of the function, input and output number format and word length for each arithmetic operation.

(B) Bit-Level Software Emulator:

We develop a software emulator which implements the target function defined in step (A) in software. Using this software emulator, we verify whether the designed hardware can actually calculate the target function with required accuracy. In this step, we also define the application program interface (API).

(C) Hardware Design:

In this step we actually write the source code which implements the pipeline processor in a hardware-description language (HDL) such as VHDL. In addition, we design the control logic and host interface logic also in some HDL. The HDL description is compiled to

Table 1. Abbreviation Glossary

API	Application Program Interface
BEM	Boundary Element Method
CAE	Computer Aided Engineering
DFT	Discrete Fourier Transform
FBCE	FPGA-Based Computing Engine
FMM	Fast Multipole Method
FPGA	Field Programmable Gate Array
GRAPE	GRAvity PipE
HDL	Hardware Description Language
LPM	Library of Parameterized Modules
LSI	Large Scale Integration
MD	Molecular Dynamics
PGDL	PGPG Description Language [defined in this paper]
PGPG	Pipeline Generator for Programmable GRAPE [defined in this paper]
PROGRAPE	PROgrammable GRAPE
SLDL	System-Level Design Language
SPH	Smoothed Particle Hydrodynamics
VHDL	VHSIC Hardware Description Language
VHSIC	Very High Speed Integrated Circuit

the configuration data for the FPGA chips by a design software, usually provided by the manufacturer of the FPGA device.

(D) Interface Software:

We develop the software on the host computer which takes care of the communication to the hardware and data format conversion between the floating-point data on the host and specialized data format used on the developed pipeline processor. The developed software should have the same API as that of the software emulator developed in step (B).

(E) Finally, we can actually use the pipeline processor with real application program, by combining the hardware, hardware configuration data, interface software and application software.

Figure 2 summarizes these steps. In these steps, we have to design, test, and debug a large amount of hardware logic and softwares. Of course, many of the softwares and hardware designs can be reused, when we develop different applications. For example, the design of the floating-point multiplier is rather generic, and can be used in almost any application. Also, it is possible to buy such design, or design software which generate floating-point arithmetic unit

Fig. 2. Traditional design flow for FPGA-based computing system. Colored items mean hardware logics and softwares that we have to develop.

with arbitrary word length, from some CAE company. However, just to understand how to use such a design, one need a deep understanding of the hardware and HDL used for that particular design. Thus, even though the reusability significantly reduce the amount of the work needed for the second and later design for one person, the initial hurdle remains rather high, for an astrophysicist who never used such software, or actually the availability of the library make the hurdle even higher, since a starter need to understand, in addition to the basics of the hardware design and HDL, the use of such libraries and particular design software for that library.

The development of the interface software is generally even more difficult than the design of the hardware, since it requires the knowledge of how the device driver softwares work in the operating system of the host computer, and infinite number of small details like how to integrate the device driver to the operating system, how to correctly generate the compiler flags to compile the device driver so that it works with the kernel installed on the host computer etc etc.

All these works combined make it almost impossible for an astrophysicist to even think

Fig. 3. Design flow with PGPG. A colored magenta item means the only file that we have to describe.

of implementing the pipeline processor on an FPGA-based computing engine.

3. The PGPG system

3.1. Basic Idea of PGPG

If we inspect Figure 2 again, we can see the fact that *all* softwares and hardware description is derived from the target function specification in step (A). Thus, it should be possible for a sufficiently smart software to generate all necessary softwares and hardware descriptions from the target function description written in some high-level language. The basic idea of PGPG is to develop such a smart software.

Figure 3 shows how the design flow changes with PGPG. After we define the target function, we write it in the high-level specification language, the PGPG description language (PGDL). The PGPG software system takes this PGDL description of the pipeline processor

Fig. 4. Block diagram of the example (artificial) pipeline.

as input, and generates all softwares and hardware descriptions. Thus, with PGPG, an astrophysicist do not have to write VHDL source code for the pipeline processor or C source codes for interface library.

In the rest of this section we illustrate how a pipeline processor is specified in PGDL and how that description is translated to actual codes.

3.2. Example Target

We consider the following (artificial) example:

$$f_i = \sum_j^n a_i a_j. \quad (i = 1, \dots, n) \quad (2)$$

This function is designed purely to show how the PGDL description and PGPG software work. Figure 4 shows the pipeline itself. “Particle” here is represented by a single scalar value a . The interaction between particles i and j is defined as the product $a_i a_j$, and we calculate sum over j to obtain the “force” on particle i . Here, we have the essential ingredients of the system: particles, their representation, functional form of interaction.

For the particle data a_i (and a_j), we use a logarithmic format, with 17 bits in total (1 bit for sign, 1 bit for zero or not, 7 bits for the integer part of logarithm and 8 bits for fractional part). The base of the logarithm is 2. This logarithmic format has the advantage that the multiplication becomes addition, so we do not need a multiplier circuit whose size is $O(m^2)$, where m is the length of the mantissa. Of course, the addition in logarithm format is more complex than that in the floating-point format. Thus, the relative advantage of the log format is not very large. The “multiplier” logic itself is generated automatically by PGPG.

In our example target function, we convert the output of multiplier to fixed-point format, so that we can accumulate it with high accuracy. This is done by a circuit provided by PGPG. Finally, converted result is accumulated by a usual fixed-point adder circuit.

The particles with index j is stored in the memory, and new data is supplied at each clock cycle. The particle with index i is fixed during one calculation, and is stored in the register within the pipeline processor.

Figure 5 shows the PGDL description of this target function. The first two lines define

```

#define ascale (pow(2.0,20.0))
#define fscale (1.0/(ascale*ascale))

/NVMP 1;
/NPIPE 2;
/JPSET iaj,aj[],log,17,8,ascale;
/IPSET iai,ai[],log,17,8,ascale;
/FOSET sfij,f[],fix,64,fscale;

pg_log_muldiv(MUL,iaj,iai,aij,17,1);
pg_conv_ltof(aij,fij,17,8,64,1);
pg_fix_accum(fij,sfij,64,64,1);

```

Fig. 5. An example of design entry file written in PGDL

Fig. 6. Block diagram of the special-purpose processor generated from a PGDL program

formulae used for the data format conversion between the internal data format (logarithmic for a_i and fixed-point for f_i). These are actually used in the next block, which defines the interface etc. The next block (lines starting with “/”) defines the register and memory layout, which also determines API. The final part describes the target function itself. It has C-like appearance, but actually defines the hardware modules and their interconnection. In the next subsection we describe the PGPG language in more detail.

3.3. The PGDL Language

In this section, we give a minimal description of the PGDL language. A full description is available in <http://progrape.jp>.

3.3.1. PGDL Target Hardware Model

Figure 6 gives the structure of the special-purpose processor generated from a PGDL “program”. It consist of the control logic, I/O logic, program-specified registers and a memory unit, and the pipeline unit. Program-specified registers are either input registers, which we call *i*-particle registers, or registers which accumulate the calculated interaction, which we call force-accumulation registers. We call memory unit *j*-particle memory.

In figure 5, the pipeline processor is specified by list of modules (lines with `pg_...`). Registers and memories are specified by lines with `/IPSET` (*i*-particle register), `/JPSET` (*j*-particle memory), and `/FOSET` (force-accumulation register).

This hardware model is general and flexible enough to express any special-purpose computer which calculates the function of the form of equation (1). We use the analogy of particles and forces, but the actual data in the *i*-particle register or *j*-particle memory need not represent physical particles, and “force” can be something completely different. For example, this hardware model can be used to describe Discrete Fourier Transform (DFT) or other types of convolution operations.

3.3.2. PGDL API Model

Currently, one PGDL program generates one function prototype, `void force(...)`, with list of arguments. The list of arguments consists of the data to be stored to *i*-particle registers, that to be stored to *j*-particle memories, and the data to be returned (the content of force accumulation registers). For the body of the function, both the emulator function and actual driver and data conversion function are generated, and the user can use either one by linking appropriate object file, without changing the source file. In figure 5, second arguments of `/JPSET`, `/IPSET` and `/FOSET` lines determine the name of the arguments which corresponds to the specified register or memory element.

3.3.3. PGDL Program Structure

A PGDL program consists of the following sections:

1. macro declaration
2. generic declaration
3. interface declaration
4. pipeline description

The macro declaration, which is the first two lines of code in figure 5, is processed by C preprocessor (`cpp`) and used just for convenience to allow the same expressions which appear in multiple places to be defined only once.

The generic declaration in figure 5 are two lines:

```
/NVMP 1;  
/NPIPE 2;
```

The first line determines the degree of the virtual multiple pipeline (Makino et al. 1997). The second one is the number of physical pipelines implemented to the current design. Thus, we can change the physical number of pipelines by just change this parameter, and the application program can make use of the parallel pipeline without any need to change the user code.

The interface declaration is the following part:

```
/JPSET iaj,aj[],log,17,8,ascale;
/IPSET iai,ai[],log,17,8,ascale;
/FOSET sfij,f[],fix,64,fscale;
```

The first argument is the name used for the registers and memories in the pipeline description, and the second one is the name used for API. the remaining arguments specifies the number formats. In this example, both a_i and a_j are in the logarithmic format, with 17 bits of the total word length and 8 bits of mantissa.

Finally, the pipeline description is the following part:

```
pg_log_muldiv(MUL,iaj,iai,aij,17,1);
pg_conv_ltof(aij,fij,17,8,64,1);
pg_fix_accum(fij,sfij,64,64,1);
```

Here, `pg_log_muldiv` generates one multiplier in the logarithmic format, which takes two inputs, `iaj` and `iai`, and calculates one output result, `aij`. The rest of arguments, 17 and 1 indicate the bit length and number of pipeline stages, respectively. The inputs are taken from the j -particle memory and the i -particle register with the corresponding names, and the output becomes the input to the next module `pg_conv_ltof`. This module converts the logarithmic format to fixed-point format. Finally, module `pg_fix_accum` accumulates the result, and the value of this accumulator, `sfij` is accessible from the application program with name `f`, as specified in `/FOSET` declaration.

3.3.4. PGDL Arithmetic Modules

The present version of PGDL supports the following two number format: (a) fixed-point format and (b) logarithmic format. For the fixed-point format PGDL supports addition (and accumulation as well), subtraction, and conversion to the logarithmic format. For the logarithmic format, multiplication, division, power functions (with rational powers), and conversion to fixed-point format are supported. Appendix 1 gives more detailed discussion of the PGDL language elements.

4. A Real Example: Gravitational Force Pipeline

In this section, we discuss the implementation of the gravitational force calculation in PGDL in detail. We chose the gravitational force calculation as the example target, because we can compare the performance and size of PGDL-generate design with hand-coded ones such

Fig. 7. Block diagram of the pipeline for gravitational force

as the pipeline design of GRAPE-5.

The pipeline to be designed calculates the gravitational force on particle i :

$$\mathbf{a}_i = \sum_j \frac{m_j \mathbf{r}_{ij}}{(r_{ij}^2 + \epsilon^2)^{3/2}} \quad (3)$$

where $\mathbf{a}_i$ is the gravitational acceleration of particle i , $\mathbf{r}_i$ and m_i are the position and mass of particle i , $\mathbf{r}_{ij} = \mathbf{r}_j - \mathbf{r}_i$, and ϵ is a softening parameter. Here we design the pipeline essentially the same as that of GRAPE-3 and GRAPE-5, to compare the performance and size.

4.1. The PGDL Pipeline Design Description

Figure 7 shows the block diagram of the gravitational force pipeline. Position data for both i -particle and j -particle are in the fixed-point format, while m_j is in the logarithmic format. After subtraction, $\mathbf{x}_j - \mathbf{x}_i$, the results are converted to the logarithmic format, and all calculations until the final accumulation are done in this logarithmic format.

Figure 8 shows the PGDL program file for the gravitational force pipeline in figure 7. One can see that each **pg** module in figure 8 directly corresponds to arithmetic units in figure 7. Actually, the PGDL description is more compact, since it allows implicit array operation, as in the case of the first line:

```
pg_fix_addsub(SUB,xi,xj,xij,NPOS,1);
```

Here, *three* modules are generated automatically, because both **xi** and **xj** are declared as the array of size 3 in the interface declaration. Also, there is no need to explicitly specify the wait (pipeline delay) modules, since the PGDL compiler inserts the necessary delay element automatically.

The top-level interface function to the application program generated from this PGDL

```

#define xscale (pow(2.0,32.0)/64.0)
#define mscale (pow(2.0,60.0)/(1.0/1024.0))
#define escale (xscale*xscale)
#define fscale (~xscale*xscale/mscale)
#define NPOS 32
#define NLOG 17
#define NMAN 8
#define NFOR 57
#define NACC 64

/NVMP 2;
/NPIPE 2;
/JPSET xj[3],x[][],ufix,NPOS,xscale;
/JPSET mj,m[],log,NLOG,NMAN,mscale
/IPSET xi[3],x[][],ufix,NPOS,xscale;
/IPSET ieps2,eps2,log,NLOG,NMAN,escale;
/FOSET sx[3],a[][],fix,NACC,fscale;

pg_fix_addsub(SUB,xi,xj,xij,NPOS,1);
pg_conv_ftol(xij,dx,NPOS,NLOG,NMAN,4);
pg_log_shift(1,dx,x2,NLOG);
pg_log_unsigned_add(x2[0],x2[1],x2y2,NLOG,NMAN,3);
pg_log_unsigned_add(x2[2],ieps2,z2e2,NLOG,NMAN,3);
pg_log_unsigned_add(x2y2,z2e2,r2,NLOG,NMAN,3);
pg_log_shift(-1,r2,r1,NLOG);
pg_log_muldiv(MUL,r2,r1,r3,NLOG,1);
pg_log_muldiv(DIV,mj,r3,mf,NLOG,1);
pg_log_muldiv(MUL,mf,dx,fx,NLOG,1);
pg_conv_ltof(fx,ffx,NLOG,NMAN,NFOR,2);
pg_fix_accum(ffx,sx,NFOR,NACC,2);

```

Fig. 8. A sample design entry file for the gravitational force pipeline written in PGDL

program has the following form:

```
void force(double x[][3], double m[], double eps2, double a[][3], int n);
```

In this example, positions of i particles and j particles are passed as a single array $\mathbf{x}$, since the same name is used in `/IPSET` and `/JPSET`. Thus, with this interface it is only possible to calculate the self-gravity of an N -body system.

4.2. Performance of Generated Pipeline

Here we report the performance of the PGDL-generated gravitational force calculation pipeline, and compare that with that of GRAPE-3 and GRAPE-5. We summarize internal number expressions for the pipeline designs in table 2.

Table 3 shows the size and performance of the generated pipeline (model G5) for several implementations with different number of pipeline stages, for two different kinds of the Altera device. The pipeline designs with different number of pipeline stages can be easily obtained by a small modification of the design entry file in PGPG. The size and maximum operation speeds

Table 2. Model

Model	Position	Internal(mantissa)	Accumulation
G3	20bit fixed	14(5)bit log	56bit fixed
G5	32bit fixed	17(8)bit log	64bit fixed
G5+	32bit fixed	20(11)bit log	64bit fixed

Table 3. Performance of the generated pipeline (model G5)

APEX20k			Stratix		
stage	size(LE)	$f_{\max}$ (MHz)	stage	size(LE)	$f_{\max}$ (MHz)
14	2735	58.92	17	2499	133.30
16	2928	60.97	19	2655	137.51
17	2925	73.78	21	2849	142.29
20	3074	74.65	23	2927	135.78
21	3064	80.33	24	2864	142.88

are those reported by Altera’s design software, Quartus II(ver 3.0). The speed grade of these devices are (-2) for APEX20k and (-5) for Stratix (fastest available at the time of the writing).

Table 4 shows the size and performance of pipelines with different accuracy (G3, G5 and G5+). One can see that both the performance penalty and size increase due to increased accuracy of G5+, compared to G3 or G5, are fairly modest.

With currently available FPGA (Stratix EP1S20), we can fit 5 G5 pipelines running at 180 MHz into one chip. The original GRAPE-5 pipeline chip, which was made 7 years ago, had two pipelines operating at 80 MHz clock. Thus, FPGA implementation of GRAPE-5 has about 5 times more speed than the original custom-chip implementation. The peak speed of one FPGA chip for GRAPE-5 pipeline is 34.2 Gflops. Of course, this large improvement over GRAPE-5 is due primarily to the advance in the semiconductor technology in the 7 years (from $0.5\mu\text{m}$ to 130 nm), but clearly indicates that FPGA-based computing engine does offer very good performance, and that PGDL provides a practical tool to implement special-purpose computers on FPGA-based computing engines.

Table 4. Performance of generated pipelines (Stratix)

Model	$f_{\max}$ (MHz)	Size (LE)	Memory (bit)	Stage
G5	181.82	3021	41k	30
G3	191.64	2369	21k	26
G5+	142.27	5082	402k	35

5. Discussion

5.1. Comparison with Other Design Methodology

In other area, such as digital signal processing, there exist many code generators that generates HDL code from a simple description. For example, a commercial package (MATLAB) generates HDL code for fixed-point filter designed using itself.

Recently, a design methodology called the system-level design has become popular. In the system-level design, the function and architecture of LSI or FPGA are described using C/C++ languages or subset of them. These languages are called the System-Level Description Language (SLDL). Using SLDL, programmers can verify functionality and performance at the early stage of the development. The design is divided into software part and hardware part. The hardware part will be synthesized to register-transfer design by a SLDL design software. The SpecC, System-C, or Handel-C are the well-known SLDLs commercially available. There are also a number of research projects to design hardware using C++/Java languages (e.g. Hutchings 1999, Mencer 2002, Tsoi 2004).

The goal of these SLDL is to describe hardware logic without using hardware description language, such as VHDL or Verilog HDL. Therefore, even if we use SLDL, we still need a detailed description of the hardware in other language like C or C++. If we consider in the traditional flow (Figure 2), we can save step (C) and (D) using SLDL, while step (B) is still required. Using PGPG, we can replace all of steps by writing a short high-level hardware description.

5.2. Planned and Ongoing Improvement of PGPG and PGDL

In this paper, we described basic concept and functions of PGPG. For those who are more interested, we put a CGI program of the current version of PGPG at a web site (<http://progrape.jp>). The CGI program generates VHDL code, user interface code, and emulator code from a PGDL description.

Although the current version of PGPG is successful in designing the pipeline for the gravitational force, its functionality is rather limited. We are currently developing the next version of PGPG that supports more functionality and multiple hardwares. For the next version, we plan to add the modules needed to design a pipeline for the SPH simulation and Boundary Element Method (BEM). BEM is one of methods to solve numerically the boundary value problem of partial differential equation (Brebbia 1978). The floating-point format with longer mantissa is needed for these applications. We are now further developing the support of the floating-point arithmetic module for PGPG. We also plan to support Xilinx FPGA chips as well as Altera chips. As the target board for Xilinx device, we use Bioler3/HORN-5 board, developed by Chiba University and RIKEN (Ito et al 2004).

This research was partially supported by the Grants-in-Aid by the Japan Society for the Promotion of Science (14740127) and by the Ministry of Education, Science, Sports, and

Appendix 1. Description of PGDL Declarations and Available Modules

Table 5 shows the features of the current version of PGP. The specification of version 1.0 is determined so that a pipeline for gravitational force, shown in section 4, can be constructed as the first step.

PGP version 1.0 supports nine parametrized modules as shown in Table 5. The bit length and the number of pipeline stage for each module can be changed by the arguments. For example, the arguments of the fixed point format adder/subtractor `pg_fix_addsub(SUB,xi,xj,xij,32,1)` indicate an operation flag(adder or subtracter), the first input, the second input, output, bit length, and number of pipeline stages, respectively, from the first to sixth argument.

Modules `pg_fix_addsub` and `pg_fix_accum` are fixed point format adder/subtractor and sign-magnitude accumulator, respectively. Modules `pg_log_muldiv` and `pg_log_unsigned_add` are logarithmic format multiplier/divider and unsigned adder, respectively. In the logarithmic format, a positive, non-zero real number x is represented by its base-2 logarithm y as $x = 2^y$. The logarithmic format has been adapted for the gravitational pipeline because it has larger dynamics length for the same word length and operation such as multiplication and square root are easier to implement than in the usual floating-point format. For more details of the logarithmic format, see GRAPE-5 paper (Kawai et al. 2000). Module `pg_log_shift` is a

logarithmic format shifter. Shift operations in the logarithmic format express square (left shift) and squared root (right shift). Module `pg_conv_ftol` is a converter from the fixed point format to the logarithmic format, and `pg_conv_ltof` is a converter from the logarithmic format to the fixed point format. In PGPG version 1.0, these modules are described partly using the Altera's LPM. A gap of delay timing is synchronized automatically by the PGPG.

Addition to the parametrized modules, five definitions are defined in PGPG version 1.0. Definitions `/NPIPE` and `/NVMP` define the numbers of (real) pipeline and virtual multiple pipeline (Makino et al. 1997), respectively. Definition `/JPSET` defines a setting for the memory unit. Definitions `/IPSET` and `/FOSET` define settings for the input and output registers in the interaction pipeline, respectively.

Appendix 2. Details of The Generated Gravitational Force Pipeline

In this appendix, we show a part of the code generated by PGPG from PGDL description of the force calculation pipeline. More complete code is obtained by a CGI program of the current version of PGPG in a website (<http://progrape.jp>).

A.2.1. VHDL Code

PGPG generates description files of the designed hardware logic in VHDL. The hardware logic includes the pipeline logic itself and its peripheral logic. Figures 9 and 10 show a part of the VHDL source files generated by PGPG (the total length is about 2800 lines). The design software provided by the FPGA manufacture creates configuration data of FPGA from the generated sources [Step (C') in figure 3]. The configuration data are downloaded into the programmable GRAPE hardware using the interface program also generated by PGPG.

A.2.2. Interface Functions

The interface software on the host computer to the programmable GRAPE hardware is composed by the C compiler of the sources generated by PGPG [Step(D') in figure 3]. Figure 11 shows a part of source files in C generated by PGPG (the total length is about 150 lines). We run the application program linked with the interface software [Step(E)].

A.2.3. Emulator Code

Figures 12 and 13 show a part of the source files generated by PGPG (the total length is 580 lines).
